

Alpha-muon sticking and chaos in muon-catalysed "in flight" d - t fusion

Sachie Kimura and Aldo Bonasera*

Laboratorio Nazionale del Sud, INFN, via Santa Sofia, 62, 95123 Catania, Italy

(Dated: February 2, 2008)

We discuss the alpha-muon sticking coefficient in the muon-catalysed "in flight" d - t fusion in the framework of the Constrained Molecular Dynamics model. Especially the influence of muonic chaotic dynamics on the sticking coefficient is brought into focus. The chaotic motion of the muon affects not only the fusion cross section but also the $\mu - \alpha$ sticking coefficient. Chaotic systems lead to larger enhancements with respect to regular systems because of the reduction of the tunneling region. Moreover they give smaller sticking probabilities than those of regular events. By utilizing a characteristic of the chaotic dynamics one can avoid losing the muon in the μ CF cycle. We propose the application of the so-called "microwave ionization of a Rydberg atom" to the present case which could lead to the enhancement of the reactivation process by using X-rays.

PACS numbers:

I. INTRODUCTION

The muon catalyzed fusion (μ CF) of hydrogen isotopes, especially d - t fusion, has been studied as a realizable candidate of an energy source at thermal energies. In the liquid D_2 and T_2 mixture, the muon assists the fusion through the formation of a muonic molecule, since the size of the muonic molecule is much smaller than that of the ordinary molecules and the fusing nuclei tend to stay closer. After the fusion process the muon is released normally and again it is utilized for another fusion. The efficiency of the μ CF is governed by the muon-sticking on the α particle which is produced in the fusion [1, 2]. The muon is lost from the μ CF cycle due to sticking(ω_0), unless it is not released successively through the interaction with the medium. The rate of the stripping of the stuck muon from the α particle is known as the reactivation coefficient R and thus the effective sticking probability(ω_s^{eff}) is determined by

$$\omega_s^{eff} = \omega_0(1 - R). \quad (1)$$

The determination of the value of R is discussed in the reference [3]. In this paper we do not take into account the medium effects which are supposed to be important to determine the precise value of R in the actual experimental setup. We rather aim to propose a method in order to enhance the reactivation process, by making use of the stochastic instability of the stuck muon in an oscillating field. For this purpose we are mainly interested in investigating the impact of the regular and chaotic dynamics [4]. The experimental value of the initial sticking ω_0 which is determined assuming the theoretical R in [3] is tabulated in the reference [5]. In the table the values of ω_0 from 7 separate measurements are smaller than theoretical estimate for the most part. The direct measurement of ω_0 has been conducted as well and gave

the $\omega_0 = 0.69 \pm 0.40 \pm 0.14$ % [2]. The temperature dependent phenomena in the muon cycling rate and in the muon loss probability, which is a function of ω_s^{eff} , have been reported on the $dd\mu$ at the temperature from 85K to 790K [6] and on the $dt\mu$ from 5K to 16K [7, 8] by measuring the fusion neutron yield and the K_α X-ray yield lately. They have observed that the muon loss probability increases and the muon cycling rate decreases as the temperature decreases. In the latter case ω_s^{eff} varies from 0.64% to 0.86 ± 0.01 % as the temperature varies from 16K to 5K. The temperature dependence in the muon loss probability is thought to be caused by a change of the reactivation coefficient R in Eq. (1) [7, 8].

At thermal energies, where the μ CF takes place, fluctuations might play a role. We investigate the influence of the fluctuations by using a semi-classical method, the constrained molecular dynamics (CoMD) approach [9]. As it is well known the molecular dynamics contains all possible correlations and fluctuations due to the initial conditions(events). In the CoMD, the constraints restrict the phase space configuration of the muon to fulfill the Heisenberg uncertainty principle. The results are given as an average and a variance over ensembles of the quantity of interest which is determined in the simulation. Especially we determine the enhancement factor of the reaction cross section by the muon as a function of the incident energy in the "in flight" fusion [10]:

$$t\mu + d \rightarrow (td\mu)^+ \rightarrow {}^4\text{He}^{++} + \mu + n + Q, \quad (2)$$

where $Q = 17.59$ MeV is the decay Q -value of this reaction. The enhancement factor of each event indicates the regularity of the system. The reaction (2) is known to give a smaller reaction rate with respect to the fusion through the formation of the molecular complex:

$$t\mu + D_2 \rightarrow [(td\mu)dee]^* \rightarrow {}^4\text{He}^{++} + \mu + n + d + 2e + Q. \quad (3)$$

(for review [11, 12]).

Subsequently we determine the initial muon sticking probability, using the phase space distribution of the muon at the internal classical turning point. The sticking probability is evaluated regardless of the difference

*Also at Libera Università Kore, Enna, Italy.

of the two reactions eq. (2) and (3) due to the fact that the Q-value is much larger than the binding energies of muonic atoms or molecules. We suppose that ω_0 is insensitive to the formation process of the muonic molecules. A distinctive feature of our study is that we do not assume the ground state of the muonic molecule as the initial state of the muonic molecules, instead we use the initial state configuration by simulating the fusion process employing the imaginary time method [13, 14, 15]. As a consequence, in fact, the muon does not stick necessarily to the ground state of the alpha particle and this fact plays an important role when we proceed to the stripping of the bound muon in the oscillating field. The chaotic dynamics could prevent the muon from being lost in the μ CF cycle due to the sticking. It is achieved by utilizing the characteristic as a nonlinear oscillator of the trapped muon on the alpha particle. We draw an analogy between the muonic He ion in the present case and microwave-ionization of Rydberg atoms [16, 17, 18], where the driven electron in the highly excited hydrogen atom in a strong microwave electric field exhibits the chaotic dynamics and is ionized. Since highly excited states in the atom, with high quantum principle number n , are in the quasi-classical regime, its stability can be explained in classical mechanics in terms of resonances. We carry out a numerical simulation by enforcing an oscillating field (linearly polarized, oscillatory electric field) on the system. This can be, likely, achieved by radiation of a coherent Synchrotron Orbital Radiation (SOR) X-ray experimentally. The oscillating force causes the resonance between the force itself and the oscillating motion of the muon around the alpha, especially when the driving frequency coincides with integer multiples of the eigen frequency of the muonic helium. In other words the muon can be stripped by controlling the chaos of the system. In passing we mention that an attempt to apply magnetic fields for the purpose of stripping from excited states of muonic helium has been proposed in [19].

This paper is organized as follows. In Sec. II we describe the theoretical framework of the CoMD for muonic molecule formation and following fusion process briefly. The relation between the enhancement factor and the chaotic motion of the muon is discussed in Sec. III. We develop in Sec. IV a formula to estimate the initial α - μ sticking probability (ω_0) and determine ω_0 . Sec. V is devoted to the discussion of a possibility of muon release. In Sec. VI we summarize the paper and mention the future perspectives of this study.

II. FRAMEWORK

The details of the framework of the CoMD is discussed in the references [9, 20, 21]. In the following we sketch the framework briefly, by applying it to the case of the reaction (2). We assume the ground-state $t\mu$ as targets at the beginning of the collision. The ground-state muonic tritium configuration in the phase space is obtained us-

ing the CoMD approach [21]. Denoting the position of the particles ($i = \mu, t$) in the phase space by $(\mathbf{r}_i, \mathbf{p}_i)$ and the relative distance and momentum between μ and t by $r_{\mu t} = |\mathbf{r}_\mu - \mathbf{r}_t|$ and $p_{\mu t} = |\mathbf{p}_\mu - \mathbf{p}_t|$ respectively, the modified Hamilton equations for the muonic tritium with constraints are

$$\dot{\mathbf{r}}_\mu = \frac{\mathbf{p}_\mu c^2}{\mathcal{E}_\mu} + \frac{1}{\hbar} \frac{\lambda_\mu^H}{\xi_H} r_{\mu t} \frac{\partial p_{\mu t}}{\partial \mathbf{p}_\mu}, \quad (4)$$

$$\dot{\mathbf{p}}_\mu = -\nabla_{\mathbf{r}} U(\mathbf{r}_\mu) - \frac{1}{\hbar} \frac{\lambda_\mu^H}{\xi_H} p_{\mu t} \frac{\partial r_{\mu t}}{\partial \mathbf{r}_\mu}, \quad (5)$$

where we use relativistic kinematics; $\mathcal{E}_i = \sqrt{\mathbf{p}_i^2 c^2 + m_i^2 c^4}$ and $U(\mathbf{r}_\mu) = -e^2/r_{\mu t}$ is the potential of the muon. The second term in the eqs. (4) and (5) represent the constraints: the phase space density of two distinguishable particles should be always equal to 1 or less [22], i.e., the terms prevent the muonic tritium from collapsing. In terms of the phase space distance, this can be written as $r_{\mu t} p_{\mu t} \geq \xi_H \hbar$, where $\xi_H = 1$ and the equal sign should be satisfied in the case of the ground state muonic atom. For this purpose λ_μ^H , the Lagrange multiplier for the Heisenberg principle, is determined depending on the distance of the muon from the triton in the phase space $r_{\mu t} p_{\mu t}$. If $r_{\mu t} p_{\mu t}$ is (smaller) larger than $\xi_H \hbar$, λ_μ^H is a positive (negative) small finite number. The approach gives the average binding energy of the ground state muonic tritium atom $BE_{t\mu} = -2.73$ keV. The value is in agreement with $BE_H(M_\mu/M_e) = -2.71$ keV, where BE_H is the binding energy of the hydrogen atom, and M_e and M_μ are the reduced masses of the electronic and muonic atoms.

Using the obtained ground-state configuration as an initial state, we perform the numerical simulation of the fusion process (2) using

$$\dot{\mathbf{r}}_i = \frac{\mathbf{p}_i c^2}{\mathcal{E}_i}; \quad \dot{\mathbf{p}}_i = -\nabla_{\mathbf{r}} U(\mathbf{r}_i) \quad (6)$$

for all the particles ($i = t, d, \mu$). As the interaction we consider a modified Coulomb interaction $U(\mathbf{r}) = \sum_{j(\neq i)} q_i q_j / r_{ij} \times (1 - e^{-br_{ij}})$, with q_i and q_j being the charges of the particles and $b = 9500 \text{ \AA}^{-1}$.

In order to treat the tunneling process in the framework of the molecular dynamics, we define the collective coordinates $\mathbf{R}^{coll}$ and the collective momentum $\mathbf{P}^{coll}$ as

$$\mathbf{R}^{coll} \equiv \mathbf{r}_d - \mathbf{r}_t; \quad \mathbf{P}^{coll} \equiv \mathbf{p}_d - \mathbf{p}_t, \quad (7)$$

with $\mathbf{r}_t, \mathbf{r}_d$ ($\mathbf{p}_t, \mathbf{p}_d$) being the coordinates (momenta) of the triton and the deuteron, respectively. To obtain the classical turning points, we first simulate the elastic collision. Subsequently we repeat the simulation in the tunneling region by switching on the collective force, which is determined by $\mathbf{F}_d^{coll} \equiv \dot{\mathbf{P}}^{coll}$ and $\mathbf{F}_t^{coll} \equiv -\dot{\mathbf{P}}^{coll}$, to enter into imaginary time [14, 15]. We follow the time evolution in the tunneling region using the equations,

$$\frac{d\mathbf{r}_{t(d)}^\Im}{d\tau} = \frac{\mathbf{p}_{t(d)}^\Im}{\mathcal{E}_{t(d)}^\Im}; \quad \frac{d\mathbf{p}_{t(d)}^\Im}{d\tau} = -\nabla_{\mathbf{r}} U(\mathbf{r}_{t(d)}^\Im) - 2\mathbf{F}_{t(d)}^{coll}, \quad (8)$$

where τ is used for imaginary time to be distinguished from real time. $\mathbf{r}_{t(d)}^{\S}$ and $\mathbf{p}_{t(d)}^{\S}$ are position and momentum of the triton (the deuteron) during the tunneling process respectively.

We assume that the fusion process occurs at small impact parameters compared with the radius of the muonic atom, i.e., we carry out the simulation of the head on collisions. Under this assumption, the penetrability of the barrier is given by [14, 15]

$$\Pi(E) = (1 + \exp(2\mathcal{A}(E)/\hbar))^{-1}, \quad (9)$$

denoting the action integral $\mathcal{A}(E)$ as

$$\mathcal{A}(E) = \int_{r_b}^{r_a} \mathbf{P}^{coll} d\mathbf{R}^{coll} \quad (10)$$

with r_a and r_b being the classical turning points. The internal classical turning point r_b is determined using the sum of the radii of the target and projectile nuclei. Similarly from the simulation without muon, we obtain the penetrability of the bare Coulomb barrier $\Pi_0(E)$. We choose the initial inter-nuclear separation 3 Å. This is much larger than the scale of the muonic tritium radius, which is of the order of 1.3 mÅ.

III. ENHANCEMENT OF THE CROSS SECTION BY THE MUONIC SCREENING EFFECT

We introduce the enhancement factor of the cross section by the bound muon f_μ

$$f_\mu = \sigma(E)/\sigma_0(E), \quad (11)$$

where $\sigma(E)$ and $\sigma_0(E)$ are the screened cross section and the bare cross section, respectively. We approximate Eq. (11) by taking the ratio of the penetrabilities in the presence and in the absence of the muon:

$$f_\mu = \Pi(E)/\Pi_0(E). \quad (12)$$

In the following discussion, the enhancement factor is referred as an indicator of the regularity of the muonic motion [4, 20]. It plays a role of a sort of order parameter and it is determined through the values obtained in the numerical simulation. In the top panel of Fig. 1 we plot f_μ as a function of the incident center-of-mass energy between the triton and the deuteron. From our simulation of the collisions using an ensemble of events, we determine the average enhancement factor $\bar{f}_\mu$ and its variance: $\Delta f_\mu = [\bar{f}_\mu^2 - \bar{f}_\mu^2]^{1/2}$. These are shown by squares and error-bars, respectively. Both the average $\bar{f}_\mu$ and its variance increase exponentially as the incident energy decreases. The dashed and dotted lines in the figure correspond to the enhancement factor f_μ in the conventional and exact adiabatic limit respectively (See Appendix). The average $\bar{f}_\mu$ is in good agreement with the

FIG. 1: Enhancement factor by the bound muon (top panel) and $\Delta f_\mu^2/\bar{f}_\mu$ (bottom panel) as functions of the incident center-of-mass energy. The arrows in the figure indicate the point where total energy is zero.

exact adiabatic limit with a screening potential $U_\mu = 8.3$ keV. This fact suggests that the enhancement mainly depends on the energies involved, i.e., the energy difference of the initial and the final atoms. Thus the problem of fusion is somewhat independent on the detail of dynamics. Even if we had prepared the entrance channel through the formation of the molecular complex eq. (3), the actual fusion cross section would not differ from the one calculated here. In particular in the limit $E \ll U_\mu$ the fusion cross section can be written from eq. (11) and eq.(A.2) as

$$\lim_{E \rightarrow 0} \sigma(E) = \lim_{E \rightarrow 0} \sigma_0(E + U_\mu) \rightarrow \frac{S(U_\mu)}{U_\mu} e^{-2\pi\eta(U_\mu)}, \quad (13)$$

where $\eta(U_\mu)$ is the Sommerfeld parameter.

In the bottom panel the ratio $\Delta f_\mu^2/\bar{f}_\mu$ versus incident energy is plotted. In the high energy limit the ratio approaches zero, i.e., the f_μ distribution becomes a δ -function ($\Delta f_\mu = 0$) and the average $\bar{f}_\mu$ approaches 1: there is no effective enhancement. In the low energy limit $\Delta f_\mu^2/\bar{f}_\mu \gg 1$, which implies that the system exhibits a sensitive dependence of the dynamics on initial conditions, i.e., occurrence of chaos. It is noteworthy that the slope of the ratio $\Delta f_\mu^2/\bar{f}_\mu$ changes at the ionization energy of the muonic tritium, which we indicated by the arrows in the figure. At this incident energy the total energy of the system is zero. The total system might be unbound at the incident energies higher than this point, while the 3-body system is bound at lower energies. We indeed verify the manifestation of chaos by plotting the Poincare surface of section with respect to the enhance-

ment factor for two events in Fig. 2. In the figure we show the surface of section for two selected events at the incident energy 0.18 keV on the x - p_x plane (FIG. 2 left panels) and on the z - p_z plane (FIG. 2 right panels), respectively. We choose the beam axis to coincide with the z -axis. At the incident energy 0.18 keV the average enhancement factor, $\bar{f}_\mu = 1.1 \times 10^{27}$ as one can see in Fig. 1. In the top panels, with $f_\mu = 4.1 \times 10^{19} (\ll \bar{f}_\mu)$ and the ratio of the external classical turning point in the presence of the muon (r_a^μ) to the one in the absence of the muon (r_a^0): $r_a^\mu/r_a^0 = 0.15$, the points show a map of a typical regular event. By contrast in the bottom panels, with $f_\mu = 2.7 \times 10^{31} (> \bar{f}_\mu)$ and the ratio of the classical turning points $r_a^\mu/r_a^0 = 0.06$, the points show the map of an irregular event: the points cover a large section of the map. The irregular muonic motion leads to smaller ex-

FIG. 2: Surface of section for 2 events, one has small f_μ (top panels) and the other has large f_μ (bottom panels), on the x - p_x (left panels) and the z - p_z (right panels) planes at the incident c.o.m energy 0.18 keV, in the atomic unit

ternal classical turning point. As a consequence it gives larger enhancements factors opposed to the previous results in the case of the electron screening [4, 20], where the irregular (chaotic) events give smaller enhancement factors. This contradiction is accounted for the fact that the system is bound in the present case at low incident energies, while in the previous case even the lowest incident energy which was investigated is much higher than the binding energy of the electrons. Therefore the chaotic dynamics of the electrons causes to dissipate the kinetic energy between the target and the projectile and lowers the probability of fusion.

We can easily deduce the reaction rate (λ^{dt}) at the liquid hydrogen density ($\rho_{LH} = 4.25 \times 10^{22} \text{ cm}^{-3}$) and at very low thermal energies $k_B T \ll U_\mu$,

$$\lambda^{dt} = \lim_{T, E \rightarrow 0} \sigma(E) |\dot{\mathbf{r}}_t - \dot{\mathbf{r}}_d| \rho_{LH} \quad (14)$$

$$= \lim_{T, E \rightarrow 0} \sigma_0(E) f_\mu |\dot{\mathbf{r}}_t - \dot{\mathbf{r}}_d| \rho_{LH}. \quad (15)$$

Using the fact that the average enhancement by the muon is written as $\bar{f}_\mu = \sigma_0(E + U_\mu)/\sigma_0(E)$ in terms of the screening potential U_μ and substituting the data in the NACRE compilation [23] for the bare reaction cross section $\sigma_0(U_\mu)$ in eq.(13),

$$\lambda^{dt} \sim \sigma_0(U_\mu) \sqrt{\frac{2U_\mu}{M_{dt}}} \rho_{LH} \sim 2.8 \times 10^4 [\text{s}^{-1}], \quad (16)$$

where we denote the reduced mass of d and t as M_{dt} and the charge symmetry in the $t+d$ system has been taken into account as it is explained in the appendix. This value is in agreement with the result obtained with an independent approach [10], $\lambda^{dt} = 0.5 \times 10^5 [\text{s}^{-1}]$. We, nevertheless, stress that this value is obtained using the average enhancement factor. As we have seen in Fig. 2 fluctuations might be extremely large and there are events which have the f_μ more than 10^4 times larger than the average $\bar{f}_\mu$. Therefore the "in flight" $d-t$ fusion rate could fluctuate as well and become comparable to the inverse lifetime of the muon. We will discuss the role of fluctuations more in detail in a future work.

IV. MUON STICKING PROBABILITY

We estimate the sticking probability of muons on the alpha particle in the exit channel:

$$(td\mu)^+ \rightarrow {}^4\text{He}^{++} + \mu + n + Q \quad (17)$$

$$\rightarrow ({}^4\text{He}\mu)^+ + n + Q. \quad (18)$$

Recall that the Q-value is 17.59 MeV, while the energies involved both in the "in-flight" reaction (2) or with molecular complex formation eq.(3) is of the order of several eV, thus we expect that the actual entrance channel for fusion is irrelevant to the following dynamics of tunneling, fusion, decay and sticking of the muon to the alpha particle.

The muon remains bound (eq. (18)), if the binding energy of the muon on an alpha particle:

$$BE_{\alpha\mu} = \frac{M_{\alpha\mu}}{2} |\dot{\mathbf{r}}_\mu - \dot{\mathbf{r}}_\alpha|^2 - \frac{2e^2}{|\mathbf{r}_\mu - \mathbf{r}_\alpha|} \quad (19)$$

is negative, in the center-of-mass system of the muon and the alpha particle. We denote the reduced mass of μ and α as $M_{\alpha\mu}$. The effect of the finite nuclear mass must be taken into account, because a muon is 206.8 times heavier than an electron. From this condition, $BE_{\alpha\mu} \leq 0$, we deduce the following equation for the angle θ between $\dot{\mathbf{r}}_\mu$ and $\dot{\mathbf{r}}_\alpha$.

$$\cos \theta \geq \frac{\frac{M_{\alpha\mu}}{2} (|\dot{\mathbf{r}}_\mu|^2 + |\dot{\mathbf{r}}_\alpha|^2) - \frac{2e^2}{|\mathbf{r}_\mu - \mathbf{r}_\alpha|}}{M_{\alpha\mu} |\dot{\mathbf{r}}_\mu| |\dot{\mathbf{r}}_\alpha|} \equiv g \quad (20)$$

The condition Eq. (20) is fulfilled when g , the r.h.s of the equation, is equal to 1 or less and for the solid angle

$\Omega = 2\pi(1 - g)$ [steradian] in the 3-dimensional space. We can therefore estimate the sticking probability by $\Omega/4\pi$, if $g \leq 1$. We point out that $|\dot{\mathbf{r}}_\alpha|$ in the equation is written as a function of the decay Q -value:

$$|\dot{\mathbf{r}}_\alpha| = \frac{m_n}{m_\alpha + m_n} |\dot{\mathbf{r}}_{\alpha n}| = \frac{m_n}{m_\alpha + m_n} \sqrt{2Q/M_{\alpha n}}, \quad (21)$$

where $\dot{\mathbf{r}}_{\alpha n} = \dot{\mathbf{r}}_n - \dot{\mathbf{r}}_\alpha$ is the relative velocity between the α and the neutron and $M_{\alpha n}$ is their reduced mass. In particular, the sticking probability can be estimated easily in some limiting cases:

CASE 1. if $|\dot{\mathbf{r}}_\mu|$ is about $|\dot{\mathbf{r}}_\alpha|$,

$$g \sim 1 - \frac{2e^2}{|\mathbf{r}_\mu - \mathbf{r}_\alpha|} \times |\dot{\mathbf{r}}_\mu|/M_{\alpha\mu} \leq 1 \quad (22)$$

Furthermore, in addition, we assume that the muon is bound in the ground state of the ^5He at the moment of the fusion(adiabatic limit), i.e., $-\frac{2e^2}{|\mathbf{r}_\mu - \mathbf{r}_\alpha|} = -10.942 \times 2.0$ keV, g is estimated to be 0.89 and thus the sticking probability is 5.6 %. In passing we mention that g is 0.352 for the reaction $d + d \rightarrow ^3\text{He} + n + 3.268$ MeV under the same assumptions with CASE 1. We deduce 32.4 % of the muon sticking probability in this case. In the case of the reaction $t + t \rightarrow \alpha + n + n + 11.33$ MeV [24], if we assume that two neutrons bring away the maximum energy 9.44 MeV, we can estimate $g = 0.84$ and the sticking probability= 7.84 % for this reaction.

CASE 2. if $|\dot{\mathbf{r}}_\mu|$ is much smaller than $|\dot{\mathbf{r}}_\alpha|$,

$$g \sim \frac{1}{2} \frac{|\dot{\mathbf{r}}_\alpha|}{|\dot{\mathbf{r}}_\mu|} \geq 1, \quad (23)$$

where we assume $-\frac{2e^2}{|\mathbf{r}_\mu - \mathbf{r}_\alpha|} \sim 0.0$. This means there is no sticking probability in this case.

We remind that muons can have higher velocity components in the quantum mechanical system. Turning to the case of our simulations, the above velocity for the bound muon is obtained as the average velocity over the ensemble of events. By inspecting each event, one could find some events which satisfy the condition $g < 1$. Indeed one of the two events shown in the top panels in Fig. 2, which is regular, has $g = 0.93 (< 1.0)$ therefore the sticking probability of this event itself is not zero (3.8 %). While the other in the bottom panels has $g = 1.9 (> 1.0)$, the sticking probability is zero. In the same way we calculated g for all the events which are created in our simulation. The resulting sticking probability of the muon on the α particle is shown with filled circles in the top panel of Fig. 3 as a function of the incident energy of the collision. At the same time, we carry out the simulation of the exit channel by creating 20000 events (randomly chosen directions of outgoing particles). The time integration of the equation of motion, Eq. (6) for all the particles ($i = \alpha, n, \mu$) is performed using Predictor-corrector integration scheme. We distinguish the muon sticking event (18) from the release

FIG. 3: Incident energy dependence of the sticking probability of the muon on the α particle. The statistical error is shown by error bars, otherwise it is within the size of the points in the figure. (top panel) Distance between the muon and the alpha particle as a function of the inter-nuclear separation (bottom panel)

event (17) by monitoring the binding energy of the muon on alpha particles Eq. (19) and the radius of the muonic ion, $\mathcal{R}_{\alpha\mu} = |\mathbf{r}_\mu - \mathbf{r}_\alpha|$. We count the events where $BE_{\alpha\mu}$ and $\mathcal{R}_{\alpha\mu}$ maintain to be negative and small respectively, up to the point where the alpha is distant enough from the neutron.

In the bottom panel in Fig. 3 typical trajectories of the distance between the muon and the alpha particle are shown as a function of the inter-nuclear separation. Among the 6 curves shown in the figure, 3 curves, which show oscillational behaviors, correspond to the sticking events. While 3 other curves increase monotonically after $R_{n\alpha}$ exceeds 0.01 Å. The horizontal straight line in the figure indicates the size of the radius of the ground state muonic ^5He atom. The obtained sticking probability is shown with open circles with error-bars in the top panel in Fig. 3. First, as one can see clearly, the result of numerical simulation agrees with the sticking probability which is calculated considering the solid angle Ω . In the figure we plot the sticking coefficient obtained from the direct measurement of ω_0 [2] with a solid line with an error bar. The resulting sticking probability range nearby the experimental value as a function of the incident energy except for several points, which have zero and relatively large sticking probability. This fact supports our assumption that ω_0 is insensitive to the formation process of the muonic molecules. We mention especially that the incident energies at which the sticking probability becomes zero is slightly below than the ionization energy of

the muonic tritium.

V. MUON STRIPPING

Before concluding the paper, we would like to suggest that the stuck muon is possibly stripped from the alpha particle, by enforcing a linearly polarized oscillatory electric wave on the system. [19] The periodic motion of the stuck muon can be expressed in terms of nonlinear oscillations. For a nonlinear oscillator the oscillating driving force, i.e., linearly polarized, in the direction z , oscillating field of frequency γ and a peak amplitude F of the field,

$$zF \sin(\gamma t), \quad (24)$$

causes the resonance between the force itself and the oscillating motion of the muon at driving frequencies which are integer multiples of the fundamental frequencies of the muon. The same concept has been applied in the ion-

FIG. 4: Time T map of a stuck muon on the r - p plane(left panels). One with the external oscillating force (right panels) with frequency γ , both in the atomic unit

ization of the Rydberg atoms in a microwave field. There the highly excited atom, Rydberg atom, is prepared by laser excitation. In the present case of muons, the muonic **He** is not stuck necessarily in its ground state. So that the muon can be ionized directly from one of such an excited state by the radiation of an electrostatic wave, otherwise the muon is, at first, prompted to an excited state and then ionized. In either cases it will be achieved using X-rays, since the fundamental frequencies for the ground and the first excited state of the muonic **He** ion

corresponds to 0.11nm and 0.44nm, respectively, in terms of the wave length. Such a X-ray is available from Synchrotron Orbital Radiation(SOR) facilities. In our numerical simulation, instead of the discontinuous frequencies, we get the proper frequency of the stuck muon for each event. The frequency is obtained by Fourier transform of the oscillation and with thus obtained frequency γ_μ we perform the simulation of stripping with above external force. In Fig. 4 we show the time T map of the oscillational motion of the muon on the r - p plane, where r is relative distance between the muon and the alpha and p is its conjugate momentum. The time T map is obtained by sampling the points in the phase space at discrete times [25]

$$t = nT \quad (T = 2\pi/\gamma, n = 1, 2, \dots). \quad (25)$$

We follow 1000 cycles of the driven oscillation in our simulation. We choose two sticking event which are shown in the bottom panel in the figure 3; one has a smaller amplitude, a tightly bound state(top panels), and the other has a larger amplitude, a loosely bound state(bottom panels). The left panels show the map of the stuck muon without external force. The map remains in a limited manifold around $r = 0$. The right panels show the case with an external force with driven frequency $\gamma = 2 \times \gamma_\mu$, where $\gamma_\mu = BE_{\alpha\mu}/\hbar$ is the angular frequency of the muon in the muonic helium ion, i.e., we are investigating the 2:1 resonance. In the case of the tightly bound muon, the muonic atom is excited in a loosely bound state and then ionized. While the tightly bound muon is ionized in one step. The muonic atom in the external oscillating field is captured into the resonance and ionized due to its stochastic instability [26]. One can see clearly that the muon is expelled from the Helium with the external oscillational force with the corresponding frequency of the unperturbed system. We point out that the μdt molecule is *not* destroyed by the external force with same frequency which we used in the above discussion.

VI. CONCLUSIONS AND FUTURE PERSPECTIVES

In this paper we discussed the alpha-muon sticking coefficient in muon-catalysed "in flight" d-t fusion. We performed numerical simulation by the Constrained Molecular Dynamics model. Especially the influence of muonic chaotic dynamics on the sticking coefficient is brought into focus. The chaotic motion of the muon affects not only the fusion cross section but also the $\mu - \alpha$ sticking coefficient. The irregular(chaotic) dynamics of the bound muon leads to larger enhancements with respect to regular systems because of the reduction of the tunneling region. Moreover they give smaller sticking probabilities than those of regular events.

We proposed a method to strip the stuck muon from the alpha particle by exposing the system in the X-ray radiation field. Its numerical experiments have been performed under an oscillating external force with the driving frequency twice as high as the angular frequency of the stuck muon and the muon has been released successfully with the selected frequency. By utilizing the chaotic dynamics one can prevent the muon from being lost in the μCF cycle due to sticking.

Based on these results, in our future study, we will develop a theory to investigate the temperature dependent phenomena, including the sticking probability and the muon cycling rate, which are reported by experimentalists [6, 7, 8]. Further quantitative analysis of the muon stripping with the oscillating force should be undertaken.

Acknowledgments

The authors acknowledge Prof. N. Takigawa for useful comments. This work was partly carried out during a short term stay of one of us (S.K.) at University of Ferrara in Italy. She is grateful to Prof. G. Fiorentini and Prof. B. Ricci for suggestive discussions and their hospitality.

APPENDIX: ENHANCEMENT FACTOR IN THE ADIABATIC LIMIT

In the section III we introduced the enhancement factor of the cross section by bound muon in terms of the barrier penetrability. In the case of the electron screening, one often assumes that the effect of the screening can be represented by a constant shift, U_μ , of the potential barrier and replaces eq.(11) by

$$f_\mu = \frac{\sigma_0(E + U_\mu)}{\sigma_0(E)}. \quad (\text{A.1})$$

U_μ is called screening potential. $\sigma_0(E)$ can be rewritten in terms of the S-factor $S(E)$ and Sommerfeld parameter $\eta(E)$, by writing down the incident energy dependence

of the barrier crossing rates explicitly [27],

$$\sigma_0(E) = \frac{S(E)}{E} e^{-2\pi\eta(E)}. \quad (\text{A.2})$$

In the limit of $U_\mu \ll E$, f_μ is approximated by

$$f_\mu = \exp \left[\pi\eta(E) \frac{U_\mu}{E} \right]. \quad (\text{A.3})$$

The merit of this conventional formula is that one can easily estimate the upper limit of the enhancement by using the adiabatic approximation in the framework of the Born-Oppenheimer approximation. In the present case of the muonic tritium target, reflecting the charge symmetry in the t+d, f_μ is obtained by assuming equally weighted linear combination of the lowest-energy “gerade” and “ungerade” wave function for the muon. [4]

$$f_\mu = \frac{1}{2} (e^{\pi\eta(E) \frac{U_\mu}{E}} + e^{\pi\eta(E) \frac{U_\mu^{(u)}}{E}}). \quad (\text{A.4})$$

it is given by substituting $U_\mu = BE_t - BE_{^5\text{He}} \sim 8.3$ keV with BE_t and $BE_{^5\text{He}}$ being the binding energy of the ground state muonic tritium and the ground state muonic ^5He respectively and $U_\mu^{(u)} = 39.6$ eV. The point is, however, that the procedure is justified only in the limit where U_μ is much smaller than E . U_μ is much larger than the low incident energies of our interest. The dotted curve in Fig. 1, which corresponds to Eq. (A.4), indeed overestimates the enhancement with respect to the exact formula:

$$f_\mu = \left(1 + \frac{U_\mu}{E} \right)^{-1} e^{-2\pi\eta(E) \left(\frac{1}{\sqrt{1+U_\mu/E}} - 1 \right)}, \quad (\text{A.5})$$

where we approximated nothing but $S(E + U_e) \sim S(E)$. To apply this formula in the present case again one needs to take a linear combination of the muonic molecular states. This is taken into account and gives the dashed curve in Fig. 1. The curve is in accord with the average enhancement factor obtained from our simulation.
